Investigation and Analysis of Damage to Buildings during the 2003 Bam Earthquake

Hossein Mostafaei* and Toshimi Kabeyasawa

Earthquake Research Institute, The University of Tokyo

Abstract

A brief statistical assessment of the seismic vulnerability of buildings in Iran is carried out. Based on the results, Iran is concluded to be one of the most vulnerable countries in the world to earthquake. A post-earthquake building damage survey was performed in Bam city, Iran, after the catastrophic earthquake of Dec. 26, 2003. Subsequently, studies were carried out on the building damage data collected. Based on the results, adobe and masonry buildings, which are the major types of structure in Bam city, were found to have suffered the highest level of damage. Reinforced concrete buildings infilled with masonry walls and masonry buildings with reinforced concrete ties, however, were structures with very low levels of damage. 624 buildings were evaluated using the European Macroseismic Scale (EMS). The results show that the low earthquake resistance of buildings in Bam city is the main reason for the high level of damage. Furthermore, macroseismic intensities are estimated for the Bam region based on the MSK scale for vulnerability class B.

Key words: Bam earthquake, adobe building, post-earthquake damage evaluation, seismic vulnerability, macroseismic intensity

1. Introduction

Iran, as one of the world's most earthquakeprone countries, has been exposed to many devastating earthquakes in past years. The 3 regions of Zagros, Alborz, and Khorasan are exposed to high seismicities. According to a tectonic hypothesis, the movement of the African plate towards the Asian plate, pushing the Arabian plateau and southwest Asia, leads to the creation of faults and ruptures in the earth's crust in a region that includes Iran. On the other hand, previous post-earthquake reconnaissance and statistical results reveal that the seismic vulnerability of residential buildings in Iran is significantly high. These 2 characteristics of Iran make it one of the most vulnerable countries to earthquakes in the world. Building damage evaluation results for the recent Iran-Bam earthquake emphasize that the low lateral resistance of existing structures, mostly masonry, is the major cause of the high level of structural damage due to earthquakes. The main goal of this paper is to present the results of a building damage inspection of the Bam-Iran earthquake, after a brief review of the seismic vulnerability of buildings in Iran.

2. Seismic vulnerability of buildings in Iran

Populated areas, primarily the major cities of Iran, are mostly located on mountains slopes or plains. The distances between mountains peaks and the centers of these cities range from about 15 to 20 kilometers. A population of 60,055,488, based on the 1996 Iran-census, inhabits Iran, which has an area of 1,648,195 km². Considering the different climatic and geographical conditions, a distribution map of population shows mountainous regions with high population densities and south and central deserts with low population densities. Figure 1 is a distribution and density map of population in various parts of the country.

Comparing the population distribution map in Fig. 1 and the seismic macrozonation hazard map in Fig. 2, for different seismic zones, reveals that the

^{*}E-mail: Mhossein@eri.u-tokyo.ac.jp (1-1 Yayoi 1 chome, Bunkyo-ku, Tokyo, 113-0032 Japan)

majority of the country's population inhabits high and very high seismic hazard zones. Based on the survey, the populations in the different zones are distributed with 800,240 inhabitants in the low hazard zone, 9,716,184 inhabitants in the moderate hazard zone, 32,979,909 inhabitants in the high hazard zone, and 16,559,155 inhabitants in the very high hazard zone, as shown in Fig. 3. In other words, 83% of the country's population inhabit regions with high and very high earthquake relative hazards.

Based on the building and housing section of Iran's statistical calendar and the 1996 census of Iran, there are 10,770,112 ordinary residential units in Iran,

Fig. 1. Distribution map of population in Iran (1996).

of which 1,594,043 units are wood, concrete, and steel structures, and 9,176,069 units are built of brick, wood, stone, cement block, tile, and clay, as shown in Fig. 4. The first group of structural systems, that is, 15 percent of existing residential units, is estimated to be designed for a seismic load. However, 85 percent of the residential units, the majority of building structures in Iran, have been constructed with brittle materials and have relatively low lateral resistance against seismic loads. Consequently, due to the very high population density in the high and very high seismic hazard zones, as well as the low lateral resistant capacity of the majority of residential buildings,

Fig. 6. Historic and instrumental seismicity of the area (IIEES, 2004).

Fig. 2. Seismic macrozonation hazard map of Iran.

Iran is one of the most vulnerable countries in the world to earthquake. This conclusion is supported by the comparison illustrated in Fig. 5. The chart shows the results of a statistical study based on the USGS database of earthquakes with 1,000 or more deaths, since 1900. The vertical axis shows the number of earthquakes that have occurred in the corresponding country in each with fatalities numbering more than 1000. Based on the results, Iran has the

Fig. 3. Population Distribution in Different Seismic Hazard Zones of Iran.

Fig. 4. Structural Types of Buildings in Iran (1996 countrywide statistical results).

Fig. 5. Seismic vulnerability of countries worldwide based on number of earthquakes in each country, each with 1,000 deaths or more (USGS, 2004).

highest seismic vulnerability in the world (Tasnimi and Mostafaei, 2001).

3. Seismicity of Bam area

Bam city is located in a high seismic hazard zone of Iran, as shown in Fig. 2. Many earthquakes have been recorded around the Bam area, but Bam city itself had no reports of great historical earthquakes before the Dec. 26, 2003 earthquake. Figure 6 shows the historic and instrumental seismicity of the area. According to the seismicity map, most major earthquakes occurred in the northwest region of Bam.

4. Strong motion record

The strong ground motions of the Bam Earthquake were recorded at 18 stations by the Building and Housing Research Center of Iran (BHRC). At Bam station, which was located in the central part of city, maximum horizontal and vertical peak ground accelerations were reported as 799 gals in EW direction and 988 gals, respectively. All 3 components of the ground accelerations are plotted in Fig. 7 as uncorrected data. Fig. 9 shows the 3 acceleration response spectra with a damping ratio coefficient of 0.05 to the critical. Among the surveyed buildings, 25 units had clear residual displacements in 1 direction. According to the results shown in Fig. 8, larger residual displacements and damage in the E-W direction are observed in 77% of the buildings, which indicate the directivity effects on ground motion.

Figures 7 and 9 show larger peak ground acceleration and response in the E-W direction compared to those in the N-S direction, which is consistent with the directions of heavy damage observed as shown in Fig. 8.

5. Structural types of building in Bam

Bam is located 193 km southeast of Kerman city on a plain between the Jebalbarez and Kabudi Mountains, and at approximately 1,100 meters above sea level. In ancient times, people lived in a citadel, which is now known as Arg-e-Bam, the gem of Iranian historical sites and one of the most beautiful buildings of the Ashkanian era. Adobe structures, with clay and straw as the main material components, comprised the major type of construction adopted in the city. The current city of Bam is located southwest of Arg-e-Bam. Based on the statisti-

Research Center (BHRC, 2004)

Fig. 8. Damage rates based on the direction in which a structure suffered more damage and experienced greater residual deformation in comparison to those of perpendiculars.

cal study, constructions in Bam can be divided into 8 types of structure. The majority of old buildings were adobe, categorized as Ad in this study, which now accounts for 8% of the all structures in the city, as shown in Fig. 10.

Almost 68% of the buildings were masonry, M

Fig. 9. Acceleration response spectra of Bam earthquake (Damping ratio: 0.05).

type or M-Ad type. The difference between M and M-Ad is the use of masonry mortar, which is cement for type M and mud-lime for type M-Ad. Figure 11 shows a masonry building in the center of the city, almost 1 km from the site where the strong ground motion accelerogram was recorded.

Reinforced masonry buildings, which are divided into 2 types, masonry with reinforced concrete ties, or M-C, and masonry with steel frame ties, or M-S, account for 14% of the structures.

Figure 12 shows a reinforced masonry building with reinforced concrete horizontal and vertical elements as ties. Type M-S also refers to a steel frame building with masonry brick walls, as shown in Fig. 13. In this type of structural system, the masonry walls give supplemental lateral resistance to the structural system and work as confined infill walls.

Steel-frame with bracing as S-B type, and steelframe, assumed with moment resistant connections, or S-F type, comprise 7% of the buildings. The S-B type is one of the most popular structural types in Iran, especially since applying the first Iranian seis-

Fig. 10. Arg-e-Bam, example of adobe structure (Ad type).

Fig. 13. Masonry with steel frame buildings, M-S type.

mic code in 1990. It is preferred by owners of conventional buildings, due to the fast and convenient construction process and economic benefits in comparison to a reinforced concrete structure (Fig. 14).

Reinforced concrete frame, the RC type shown in Fig. 15, and special steel frame with masonry walls, M-S-F type shown in Fig. 16, occupy the remaining 3% of structures in the city of Bam. The proportions of the different structural types in Bam city are illustrated in Fig. 17. It can be inferred from the figure that 24% of the surveyed buildings (M-C & M-S, S-B & S-F, and RC & M-S-F) in the city have structural systems that are defined in the Iranian seismic code as systems with a seismic resistant design.

6. Damage evaluation

In this survey, building samples were selected in Bam city and 4 nearby villages (Esfikan, PoshtRood, KhajeAskar, and Baravat), by applying a simple random sampling method to have an equal chance of building selection in the population. Bam area was divided into 9 zones according to their overall average of estimated building age, population density, and overall damage grade. All data collected are listed in Table 1. The overall damage grades and the density of population in each zone were estimated from aerial photos taken soon after the earthquake, and the corresponding damage evaluation results, published by National Cartographic Center of Iran (NCCI, 2003). Figure 18 illustrates the 9 zones selected and the number of buildings surveyed in the corresponding zones. Zone 1 is the oldest part of Bam city, in which 70% of the buildings are more than 30 years old. Although some RC and steel frame structures were observed in zone 1, adobe and masonry buildings were the most common structures in this zone. The numbers of buildings surveyed in each zone were selected according to the population density in the corresponding zone. Zones 1, 2, and 3 had very high population densities compared to that of the zone 4, which is mostly covered with palm and citrus trees. Therefore, the number of building samples in zone 4 is less than the other zones, as shown in Fig. 18. In the figure, zone i (e.g. zone 1), refers to the zone number and the number at the right side (e.g. 116 for zone 1) regarding the number of buildings surveyed in that zone. The epicenter location in the figure was

Fig. 14. Steel frame structures with bracing, S-B type.

Fig. 15. Two-story RC structure, RC type.

Fig. 16. Special steel frame-masonry structures, M-S-F type.

derived from aftershock observations reported by Suzuki, *et al.* (2004). In this study, 624 buildings listed in Table 1 were evaluated according to the European Macro-seismic Scale (EMS) by Grunthal G., (1998). Damage grades on the EMS scale are classified as grade 1: negligible to slight damage, grade 2: moderate damage, grade 3: substantial to heavy damage, grade 4: very heavy damage, and grade 5: destruction. Figure 19 illustrates the survey results of total structural damage grades for the different types of building. The figure indicates that almost 70% of the buildings in Bam city suffered very heavy damage or complete destruction, with grade 4 or grade 5, and only 10% of the buildings in the city were observed with slight damage or grade 1.

A further estimation was made to obtain damage grades for different types of structure. Figure 20 shows the outcomes of the study. As indicated by the figure, masonry buildings, types M and M-Ad, and also adobe constructions, type Ad have the highest rates of damage among the different types of structure. The main reason for such a high level of destruction is the very low lateral load-bearing capacity of their structural systems against seismic loads. On the other hand, reinforced masonry buildings such as type M-C and M-S had considerably lower damage rates compared to those of masonry or adobe buildings. These results emphasize the importance of reinforcing masonry buildings, which is also outlined in the seismic code of Iran.

Steel frame with bracing, S-B type, is the other type of structure that has in low damage rates. This type of structure is very popular in Iran. The 2 main problems observed for S-B type structures might be imperfect connections welding or insufficient lateral bracing system for earthquake resistance, which results from less attention being given to quality control for construction process and structural design. The reinforced concrete structure, RC type, was the structural system used in approximately 2% of construction in Bam. The damaged RC buildings, observed in Bam, had low rates of transfer reinforcement in the columns, and low quality control in the construction process and structural element design. In some of the new and quite well designed buildings, no major cracks or damage were observed in the structural elements. Which might imply that the buildings had almost linear performance during the earthquake. However, based on the minimum design base shear coefficients obtained from the Iranian code, nonlinear performance is expected of such buildings due to the earthquake. Examples of structures with this kind of response are the RC buildings of telephone centers in Bam city (in Zone 1 of Fig. 18, the same zone as the strong motion station's zone) and Baravat village (in Zone 8), as shown in Figs. 21 and 22, respectively. The steel structure of Bam Azadi hotel (in Zone 4) also performed without significant structural damage, as shown in Fig. 23. Based on these observations, it is estimated that the effects of infill masonry walls might be an important factor for the almost linear response of this kind of frame structure. To find the answer, in addition to the statistical damage evaluation presented, a case study of a 3D nonlinear time history analysis for the RC building of the Telephone Center in Bam city,

which was subjected to the strong motion record, was carried out. This results are presented in a separate paper.

The first Iranian code of practice for seismic resistant designs of buildings was applied in 1990 as a mandatory code, and the second edition was published in 1999. Therefore, the buildings surveyed were also sorted by year of construction to identify the effects of code practicing.

Figure 24 shows damage rates for buildings sorted by construction date. As the statistical results indicate, 77% of the buildings in the city were constructed before 1990, the mandatory year of the seismic code, and suffered very high rates of damage. However, among buildings built from 1990 and after the second edition of the seismic code was published in 1999, the damage rates were significantly reduced, which shows efficient results of applying the seismic code.

7. Damage distribution in Bam city

The 4 zones of Bam city, zones 1 to 4 in Fig. 18, are shown magnified in Fig. 25. This map shows the zoning map of building damage distribution, as well as overall damage ratios in each zone based on data collected only in Bam city. By comparing Figs. 18, 25, and 26-a, it can be inferred that the damage rates decreased significantly in zones 4, 8, and 9, although they are not far from the epicenter. According to the results, zone 3 followed by zone 1 show the highest damage rates in the area. However, zone 2, which is located between zones 1 and 3, shows lower damage ratios. Figure 26-b illustrates damage ratios in Zones 1 to 4 for only one type of structure, masonry buildings. Based on the figure, zone 2 again has lower rates of damage than zone 1 and zone 3. Therefore, the different damage rates might be due to other factors such as fault mechanism. Further study is recommended on this outcome.

8. Estimation of macroseismic intensity

A MSK intensity contours map was drawn from building damage grades, based on EMS98 definitions (Grunthal, 1998). EMS98 is a macroseismic scale proposed by the European Seismological Commission of International Association of Seismology and Physics of Earth's Interior (IASPEI) in 1998, which was based on a modification of the MSK scale (1964). Building

Fig. 24. Damage rates based on year of construction.

Fig. 25. Zoning map of building damage distribution in Bam city.

vulnerability classes are defined on the improved scale of EMS98 in a similar way to those of the MSK scale from A to F shown in Fig. 27.

Damage definitions in EMS98 were applied to obtain macroseismic intensities for the Bam region. To estimate macroseismic intensities, first the evaluated buildings are sorted according to type, A to F, and their damage rates, 1 to 5, based on the EMS98 scale. Then, in each selected area, corresponding to each type of building, the damage rates are computed for each damage grade. Damage rate, for damage grade i of the selected structural type, is defined as the number of buildings with damage i, divided by the total number of buildings in the selected area. Table 2 shows the relation between MSK intensity and damage rates for the various vulnerability classes and damage grades (EMS98).

Because the masonry structure was the most common type of building in Bam city and the nearby villages, almost 70% of the surveyed buildings, it was

Fig. 26-a. Ratio of damage grades in different zones.

Fig. 26-b. Damage rates in zones 1 to 4 based on damage ratios of masonry buildings.

selected as the structural type of vulnerability class B for the intensity estimation. Therefore, the third column of Table 2 is applied for this study. The other structural types were not chosen for the macroseismic estimation, because the number of buildings surveyed of each type was not sufficient to achieve an acceptable result under the assessment method. Both masonry type M and type M-Ad were assumed to have the same class of vulnerability as class B in EMS98 scale (Table 2). The results of the macroseismic intensity estimations, using the above approach, are illustrated in Fig. 28.

To estimate the intensities, Bam city and nearby villages were divided into bins with the network shown in Fig. 28. For the surveyed buildings located in each bin, damage rates corresponding to the each damage grade were computed and correlated with MSK intensity, according to Table 2. The correlated MSK intensity was selected as the estimated intensity for the corresponding bin. Finally, the contours were drawn using an interpolation method. The outcomes were modified considering the location of

MSK scale, which is about X on the Modified Mercalli Scale. The conversion can be applied using Fig. 29. According to the figure, the maximum acceleration for intensity X may be estimated at between 800 cm/s^2 s² and $1,000 \text{ cm/s}^2$, which are almost in the same ranges as those recorded.

Conclusions

Based on the brief statistical analysis of historical earthquake damage and building types, Iran is ranked as one of the most seismically vulnerable countries in the world. A post-earthquake evaluation of damage to 624 buildings after the Iran-Bam earthquake was carried out in this study. The majority of the demolished buildings in the city were masonry and adobe structures without a seismic design. On the other hand, masonry buildings with reinforcements or ties, even if they were not well designed, experienced significantly low rates of damage due to the effects of infill walls and confinement. Input directivity was observed from the damage direction of buildings surveyed, with larger residual displacements and damage in the east-west direction. Low damage rates for buildings constructed after applying the seismic code show progress in reducing the seismic vulnerability of buildings in the area. A number of newly constructed RC and steel frame

structures with seismically resistant designs, were observed to have significantly low rates of damage in the high-intensity zones, which might be due to the effects of masonry infill walls. To find answers for the observed responses, a further study is being carried out. The results will be presented in another paper. Macroseismic intensities were estimated for the Bam area on the MSK scale using EMS98 and the damage rates of the surveyed masonry structures. The macroseismic intensity estimation results for the Bam region revealed almost the same range of converted accelerations as that of the recorded strong ground motion.

Table 1–14. (continued)

Total No.: Total number of buildings, No.: Local number of buildings for observation, Area: Location of Building based on the below Map, Location Street: Name of Street, Year Built: Year constructed as estimated by the investigator, No. of Stories: Number of stories of the building, Direction: definitions: 1=Entrance of the Building faces west, 2=Entrance of the Building faces East, 3=Entrance of the Building faces south, 4 Entrance of the Building faces North, Use of Structure: The Building is used as: A-Apartment Building, Ad-Administrative Building, AS-Apartment-Shop Building, C-Commercial Building, E-Educative Facility, O-Others.

Structure: Type of Structure: Ad=adobe structure, M=Masonry, M-Ad Masonry with adobe mortar, M-C=Masonry with RC ties, M-S=Masonry with steel ties, S-B=Steel frame structures with bracing, RC=Reinforced Concrete, M-S-F=steel frame-masonry structure.

Damage Rate: Damage grades in the EMS scales; grade 1: negligible to slight damage, grade 2: moderate damage, grade 3: substantial to heavy damage, grade 4: very heavy damage, and grade 5: destruction.

Photo No.: Number of related digital photo file. The photos can be provided by the authors on request.

Buildings Locator Map: A networked map of Bam city and four nearby villages.
